Abstract: The current study aimed to examine whether the *APOE* ε4 allele, associated with dementia with Lewy bodies (DLB), and possibly with dementia in Parkinson's disease (PD), is also associated with idiopathic REM sleep behavior disorder (RBD). Two SNPs, rs429358 and rs7412, were genotyped in RBD patients (n=480) and in controls (n=823). *APOE* ε4 allele frequency was 0.14 among RBD patients and 0.13 among controls (OR=1.11, 95% CI 0.88-1.40, *p*=0.41). *APOE* ε4 allele frequencies were similar in those who converted to DLB (0.14) and those who converted to PD (0.12) or multiple system atrophy (0.14, *p*=1.0). The *APOE* ε4 allele is neither a risk factor for RBD nor it is associated with conversion from RBD to DLB or other synucleinopathies.

1. Introduction: Rapid eye movement (REM) sleep behavior disorder (RBD) is currently the strongest clinical prodromal feature preceding the development of an overt synucleinopathy, including Parkinson's disease (PD), dementia with Lewy bodies (DLB) or multiple system atrophy (MSA) (Iranzo, et al., 2014). One of the strongest genetic factors associated with DLB is the *APOE* epsilon4 (ε4) allele (Pickering-Brown, et al., 1994), and PD patients who carry this allele may be at increased risk for developing dementia. Since both RBD and the *APOE* ε4 allele are possibly associated with DLB, and with dementia in PD patients, we aimed to examine whether the *APOE* ε4 allele is associated with RBD and conversion to DLB. See Supplementary file for detailed introduction and full list of references.

2. Methods: The study population included idiopathic RBD patients (n=480) and controls (n=823) of European ancestry. RBD patients were diagnosed using clinical interview and polysomnography according to the ICSD-2 (International Classification of Sleep Disorders, version 2) criteria. The control group was composed of 253 elderly controls (age 59.5±9.8 years, matched to the available age at onset (AAO) of RBD, n=307, age 59.2±11.5), 510 young controls (age 34.0±6.5 years), and additional 60 controls with no available data on age. All control groups had nearly identical frequencies of the *APOE* ε4 allele (0.13, 0.13 and 0.14, respectively), which allowed us to analyze all controls combined. All

individuals signed informed consent forms at enrollment, and the study protocols were approved by the respective institutional review boards. DNA was extracted using a standard salting-out protocol. Two single nucleotide polymorphisms (SNPs), rs429358 and rs7412, were genotyped using TaqMan SNP genotyping assays. Genotypes were called using the QuantStudio™ 7 Flex Real-Time PCR System and Software (v 1.0). Goodness of fit test with one degree of freedom was applied to look for deviation from the Hardy-Weinberg equilibrium (HWE) among the controls. Differences in *APOE* allele or carriage frequencies were analyzed using the Fisher's exact test, and differences in continuous variables were analyzed using t-test. A logistic regression model with age and sex as covariates was also applied. All statistical analysis was done using SPSS statistics V.23 (IBM Inc.). Detailed methods can be found in the supplementary file.

3. Results: The allele frequency of *APOE* ε4 was 0.14 among RBD patients and 0.13 among controls (OR=1.11, 95% CI 0.88-1.40, *p*=0.41). Overall, 25.8% of RBD patients carried at least one *APOE* ε4 compared to 23.0% among controls (*p*=0.25, Fisher's exact test), and there were more homozygous carriers of the *APOE* ε4 allele among controls (3.2%) as compared to RBD patients (2.7%). Logistic regression model adjusted for age and sex also demonstrated lack of association between *APOE* ε4 allele carriage and risk for RBD (OR = 1.25, 95% CI 0.87-1.79, *p*=0.23). There was no difference in AAO when comparing carriers (n=88) and non-carriers (n=219) of the *APOE* ε4 allele (59.1 ± 8.4 vs. 59.3 ± 12.6 years, respectively, *p*=0.92, t-test). A total of 140 RBD patients (29.2%) were reported to have converted to either PD (n=98, 70% of the converters), dementia/DLB (n=28, 20%) or MSA (n=14, 10%). The carrier frequencies of one or more *APOE* ε4 in these groups were similar; 23.5%, 25.0% and 28.6%, respectively (*p*=0.91), and the allele frequencies were 0.12, 0.14 and 0.14 (*p*=1.0). The *APOE* ε4 allele frequency among those that did not convert was slightly higher, 0.15 (Table 1), with a total of 26.5% carriers of at least one *APOE* ε4 allele, compared to 24.3% among those who converted (*p*=0.65). More detailed results can be found in the supplementary file.

4. Discussion: Although RBD is a strong risk factor for developing DLB, and although DLB was reported to be associated with the *APOE* ε4 allele, our results demonstrate lack of association between the *APOE* ε4 allele and RBD or its age at onset. These and previous results further suggest that RBD may have a distinct genetic background; it is associated with *GBA* mutations (Gan-Or, et al., 2015b), but unlike PD it is not associated with *LRRK2* mutations (Fernandez-Santiago, et al., 2016), and unlike DLB it is not associated with the *APOE* ε4 allele. Thus far, *GBA*, *SCARB2*, and potentially *SNCA* (Gan-Or, et al., 2015a) overlap between RBD, PD and DLB (Supplementary Figure 1, see Supplementary file). Whether RBD has additional, unique genetic factors that were not identified in PD or DLB cohorts is still to be determined. Our current study identified similar frequencies of *APOE* ε4 allele in those who progressed to PD, DLB and MSA, suggesting that *APOE* alleles do not affect the type of subsequent synucleinopathy. Our study has some limitations, and a more detailed discussion including full list of references can be found in the supplementary file. Our results support a distinct genetic background for RBD-associated neurodegeneration, probably suggesting a specific genetic association with synucleinopathy rather than tauopathy/amyloidopathy.

Abstract

A significant proportion of individuals with REM sleep behavior disorder (RBD) will progress to dementia with Lewy bodies (DLB) and Parkinson's disease (PD). We aimed to examine whether the *APOE* ε4 allele, associated with DLB, and possibly with dementia in PD, is also associated with idiopathic RBD. The two SNPs tagging the different *APOE* alleles (rs429358 and rs7412) were genotyped in individuals who were initially diagnosed with RBD (n=480) and in controls (n=823). *APOE* ε4 allele frequency was 0.14 among RBD patients and 0.13 among controls (OR=1.11, 95% CI 0.88-1.40, *p*=0.41), and this lack of association remained after adjustment for age and sex. Furthermore, allele frequencies of *APOE* ε4 were similar in those who converted to DLB (0.14) and those who converted to PD (0.12) or multiple system atrophy (0.14, *p*=1.0). The *APOE* ε4 allele is neither a risk factor for RBD nor it is associated with conversion from RBD to DLB or other synucleinopathies.

Key words: REM sleep Behavior disorder, APOE

Introduction

Rapid eye movement (REM) sleep behavior disorder (RBD), characterized by lack of muscle atonia and enacting of dreams during REM sleep, is currently the strongest clinical prodromal feature preceding the development of an overt synucleinopathy. With long term follow-up, more than 80% of individuals with idiopathic RBD developed either Parkinson's disease (PD), dementia with Lewy bodies (DLB) or multiple system atrophy (MSA) (Iranzo, et al., 2014,Schenck, et al., 2013). It was suggested that RBD may define a subtype of PD patients (Fereshtehnejad, et al., 2015,Gagnon, et al., 2004) with cognitive decline (Gagnon, et al., 2009,Vendette, et al., 2007), dementia (Anang, et al., 2014), hallucinations (Sixel-Doring, et al., 2011) and autonomic dysfunction (Postuma, et al., 2008), as compared to PD patients without RBD. In addition, pathological studies in brains of PD patients with and without RBD demonstrated a more widespread α-synuclein accumulation in those associated with RBD (Postuma, et al., 2015a).

If indeed RBD represents a subtype of PD, or a subtype of synucleinopathy, it is possible that it has specific genetic background. A preliminary study that examined the association of RBD with several genetic risk factors for PD identified an association mainly with *MAPT* and *SCARB2*, and marginal or lack of association with other markers (Gan-Or, et al., 2015a). A recent study suggested that RBD is associated with mutations in *GBA* in both idiopathic RBD and PD cohorts (Gan-Or, et al., 2015b). This association was stronger than the association of *GBA* mutations with PD in a similar population (Noreau, et al., 2011), suggesting that *GBA* may be one of the genetic factors that is more specific to RBD. Furthermore, the association of *GBA* mutations with DLB (Nalls, et al., 2013) also seems to be stronger than the association with PD (Sidransky, et al., 2009). Conversely, mutations in *LRRK2* were not associated with RBD (Fernandez-Santiago, et al.,

2016,Pont-Sunyer, et al., 2015,Saunders-Pullman, et al., 2015), further supporting the hypothesis that RBD has a distinct genetic background.

One of the strongest genetic factors associated with DLB is the *APOE* epsilon4 (ε4) allele (Pickering-Brown, et al., 1994), and PD patients who carry this allele may be at increased risk for developing dementia (Pankratz, et al., 2006), although negative results were also reported for these associations (Jasinska-Myga, et al., 2007,Lovati, et al., 2010). Since both RBD and the *APOE* ε4 allele are possibly associated with DLB, and with dementia in PD patients, we aimed to examine whether the *APOE* ε4 allele is associated with RBD and conversion to DLB.

Methods

Population

The study population included consecutively recruited, unrelated idiopathic RBD patients (n=480) and controls (n=823) of European ancestry. RBD patients were collected by collaborators from the international RBD study group and were diagnosed using clinical interview and polysomnography according to the ICSD-2 (International Classification of Sleep Disorders, version 2) criteria.(Thorpy, 2012) The control group was composed of 253 elderly controls (age 59.5±9.8 years, matched to the available age at onset (AAO) of RBD, n=307, age 59.2±11.5), 510 young controls (age 34.0±6.5 years), and additional 60 controls with no available data on age. However, all control groups had nearly identical frequencies of the *APOE* ε4 allele (0.13, 0.13 and 0.14, respectively), suggesting lack of age-effect, which allowed us to analyze all controls combined. All individuals signed informed consent forms at enrollment, and the study protocols were approved by the respective institutional review boards.

Genotyping

DNA was extracted using a standard salting-out protocol. To determine the *APOE* haplotypes, two tagging single nucleotide polymorphisms (SNPs), rs429358 and rs7412, were genotyped using TaqMan SNP genotyping assays (C___3084793_20 and C____904973_10, respectively, ThermoFisher Scientific Inc.) according to the manufacturer's instructions. Genotypes were called using the QuantStudio™ 7 Flex Real-Time PCR System and Software (v 1.0). Carriers of T in rs429358 and T in rs7412 were determined as carriers of the ε2 allele, carriers of T in rs429358 and C in rs7412 were determined as carriers of the ε3 allele, and carriers of C in rs429358 and C in rs7412 were determined as carriers of the ε4 allele. Of this cohort, the *GBA* gene was sequenced in 265 RBD patients (Gan-Or, et al., 2015b), and nine PD-associated SNPs were genotyped in 261 patients (Gan-Or, et al., 2015a).

Statistical analysis

Categorical variables are presented as percentage or frequencies, whereas continuous variables are presented as mean ± standard deviation. Goodness of fit test with one degree of freedom was applied to look for deviation from the Hardy-Weinberg equilibrium (HWE) among the controls. Differences in *APOE* allele or carriage frequencies were analyzed using the Fisher's exact test, and differences in continuous variables were analyzed using t-test. To further avoid a potential bias due to age, and since sex distribution was different among patients with RBD vs. controls, a logistic regression model with age and sex as covariates was also applied. All statistical analysis was done using SPSS statistics V.23 (IBM Inc.).

Results

Lack of association between the *APOE* ε4, RBD risk and its age at onset

Table 1 details the different *APOE* alleles in RBD patients and controls. The frequency of the two SNPs defining the *APOE* alleles did not deviate from HWE. The allele frequency of *APOE* ε4 was 0.14 among RBD patients and 0.13 among controls (OR=1.11, 95% CI 0.88-1.40, *p*=0.41). Overall, 25.8% of RBD patients carried at least one *APOE* ε4 compared to 23.0% among controls (*p*=0.25, Fisher's exact test), and there were more homozygous carriers of the *APOE* ε4 allele among controls (3.2%) as compared to RBD patients (2.7%). Logistic regression model adjusted for age and sex also demonstrated lack of association between *APOE* ε4 allele carriage and risk for RBD (OR = 1.25, 95% CI 0.87-1.79, *p*=0.23). Data on age at onset (AAO) of RBD was available for 307 individuals, and there was no difference in AAO when comparing carriers (n=88) and non-carriers (n=219) of the *APOE* ε4 allele (59.1 ± 8.4 vs. 59.3 ± 12.6 years, respectively, *p*=0.92, t-test).

The *APOE* ε4 allele is not associated with conversion to PD, DLB or MSA.

Since most of the patients in our cohort are being followed-up longitudinally, we examined whether the *APOE* ε4 allele is associated with conversion to either PD, dementia/DLB, or MSA. A total of 140 RBD patients (29.2%) were reported to have converted to either PD (n=98, 70% of the converters), dementia/DLB (n=28, 20%) or MSA (n=14, 10%). The carrier frequencies of one or more *APOE* ε4 in these groups were similar; 23.5%, 25.0% and 28.6%, respectively (*p*=0.91), and the allele frequencies were 0.12, 0.14 and 0.14 (*p*=1.0). The *APOE* ε4 allele frequency among those that did not convert was slightly higher, 0.15 (Table 1), with a total of 26.5% carriers of at least one *APOE* ε4 allele, compared to 24.3% among those who converted (*p*=0.65).

Discussion

Although RBD is a strong risk factor for developing DLB (Iranzo, et al., 2014,Postuma, et al., 2015b). and although DLB was reported to be associated with the *APOE* ε4 allele (Kobayashi, et al., 2011,Lane, et al., 2009,Pickering-Brown, et al., 1994), our results demonstrate lack of association between the *APOE* ε4 allele and RBD or its age at onset. These and previous results (Fernandez-Santiago, et al., 2016,Gan-Or, et al., 2015a,Gan-Or, et al., 2015b,Saunders-Pullman, et al., 2015) further suggest that RBD may have a distinct genetic background; it is associated with *GBA* mutations (Gan-Or, et al., 2015b), but unlike PD it is not associated with *LRRK2* mutations (Fernandez-Santiago, et al., 2016,Saunders-Pullman, et al., 2015), and unlike DLB it is not associated with the *APOE* ε4 allele. Thus far, *GBA*, *SCARB2,* and potentially *SNCA* overlap between RBD, PD and DLB (Figure 1) (Bras, et al., 2014,Gan-Or, et al., 2015a,Gan-Or, et al., 2015b). Whether RBD has additional, unique genetic factors that were not identified in PD or DLB cohorts is still to be determined.

Since PD patients with RBD are likely to develop dementia and hallucinations (Anang, et al., 2014,Sinforiani, et al., 2008), eventually presenting a phenotype similar to DLB, and based on the current and previous genetic and post-mortem results (Postuma, et al., 2015a), we hypothesize that RBD-associated synucleinopathy (the central common area in Figure 1) is the same clinical-pathological entity, whether it is defined as parkinsonism first with subsequent dementia and hallucinations, or whether it is defined as DLB with subsequent parkinsonism. In that sense, RBD can be considered as a marker for diffuse synucleinopathy, which may be a better description of the disease than DLB or PD with dementia. Neuropathological data from *GBA* mutations carriers

also demonstrated a more diffuse synucleinopathy (Choi, et al., 2011,Neumann, et al., 2009,Wong, et al., 2004), further supporting this notion. However, others suggest that PD and DLB should remain separate entities, at least until better genetic, molecular and clinical data will allow better definitions of these diseases and their potential subgroups (Boeve, et al., 2016). It is possible that stochastic events, or other genetic or environmental factors, determine whether α-synuclein will first be deposited in brain areas associated with dementia and later in the areas associated with parkinsonism, or vice versa (Lai, et al., 2008,Lai and Siegel, 2003). The observation that α-synuclein can spread in the brain in a prion-like fashion (Bernis, et al., 2015,Danzer, et al., 2009,Freundt, et al., 2012) may support a stochastic progression hypothesis, yet additional neuro-pathological studies are needed to examine this possibility. Therefore, there are two possible explanations for the lack of association between the *APOE* ε4 allele and conversion to DLB in our cohort. First, as previously suggested (Bras, et al., 2014), it is possible that the association of the *APOE* ε4 allele with DLB is due to the component of DLB patients who also have a tauopathy, and that the association of RBD with DLB is with those who have more pure synucleinopathy. Alternatively, since the majority of our cohort had not yet converted to an overt synucleinopathy, it is possible that once a larger number would convert, an association between *APOE* ε4 allele and conversion to DLB may arise. Hence, a follow-up study will be needed to determine this possibility.

The association of RBD with the more devastating synucleinopathy, MSA, also necessitates more study. Whether unique genetic or environmental factors affect the risk to progress from RBD to MSA is still unknown. Our current study identified similar frequencies of *APOE* ε4 allele in those who progressed to PD, DLB and MSA, suggesting that *APOE* is not one of these factors. Interestingly, a recent study suggested that *GBA* mutations are associated with

MSA as well,(Mitsui, et al., 2015) however this observation is awaiting replications in additional cohorts.

Our study has some limitations. The control population was younger than the RBD group. To tackle this limitation, we took two approaches. First, we demonstrated that the frequencies of the *APOE* ε4 allele were similar across generations (i.e. in the elderly and young control groups), which rules out a potential bias. Furthermore, we also performed a logistic regression model with adjustment for age, which further demonstrated lack of association between the *APOE* ε4 allele and RBD. Another possible limitation would stem from RBD patients being recruited in multiple centers, which could have led to a potential population dependent bias if some cohorts are enriched in *APOE* ε4 allele carriers. However, since the frequencies of the *APOE* ε4 allele were similar across centers, this possibility was ruled out.

To conclude, our results support a distinct genetic background for RBD-associated neurodegeneration, probably suggesting a specific genetic association with synucleinopathy rather than tauopathy/amyloidopathy. To examine the hypotheses raised by the current and previous work, larger studies are necessary, including genome wide association and next-generation sequencing studies focusing on RBD, and comparing them to results from PD, DLB and MSA.

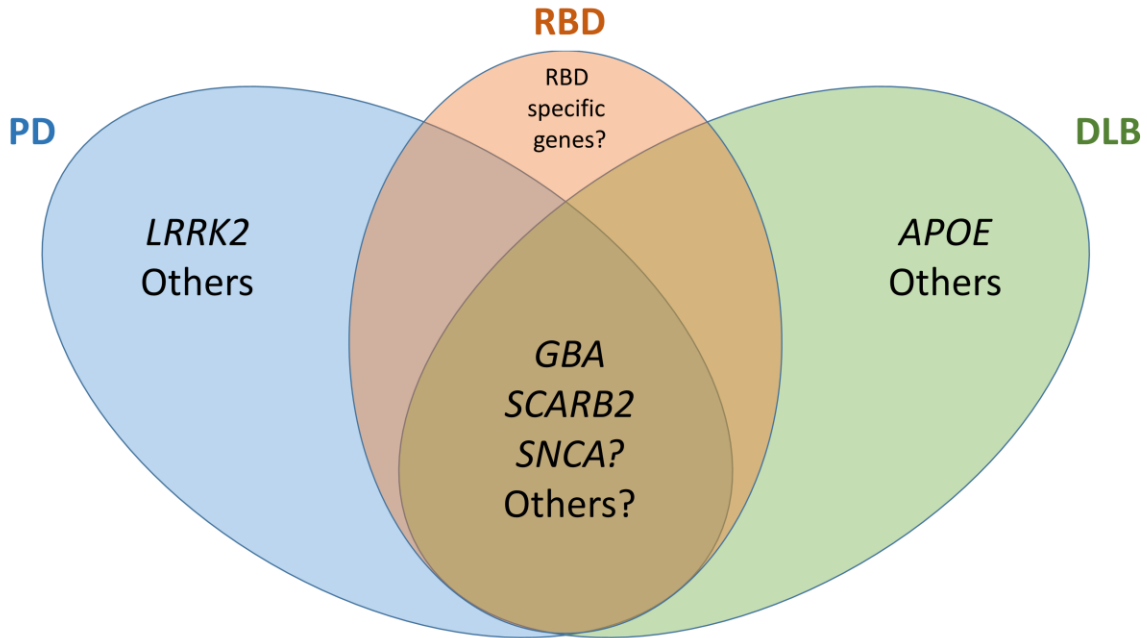

Figure 1. Venn diagram of the genetic overlap between PD, DLB and RBD.

While *GBA* mutations, *SCARB2* and possibly *SNCA* variants are associated with all three conditions, other genetic variants such as *APOE* ε4 in DLB and *LRRK2* mutations in PD are distinctively associated with each condition but not with RBD. It is therefore likely that RBD-associated neurodegeneration (the overlapping area of PD, DLB and RBD) may have distinct genetic background. While thus far no genetic variants that are uniquely associated with RBD were discovered, it is possible that such genetic risk factors do exist, and that they were not discovered in PD/DLB studies since RBD cases are diluted within the cohorts used to study these diseases.
